\(\alpha\)-decay spectroscopy of the new isotope \(^{192}\text{At}\)

PHYSICAL REVIEW C 73, 024317 (2006)

Decay properties of the new neutron-deficient nuclide \(^{192}\text{At}\) have been studied in the complete fusion reaction \(^{144}\text{Sm}(^{51}\text{V}, 3n)^{192}\text{At}\) at the velocity filter SHIP. Two isomeric states with half-lives of 88(6) ms and 11.5(6) ms, respectively, and with complex \(\alpha\)-decay schemes were identified in \(^{192}\text{At}\). The decay pattern of one of the isomers suggests that it is based on the oblate-deformed \(\pi 2f_{7/2} \otimes \nu 1i_{13/2}\) configuration, which confirms the expected onset of deformation in the At isotopes by approaching the neutron midshell at \(N = 104\).

I. INTRODUCTION

Theoretical calculations have suggested shape coexistence and the onset of strong ground-state deformation in the extended region of nuclei just above the proton shell closure at \(Z = 82\) and close to the neutron midshell at \(N = 104\), see for example Ref. [1]. Unfortunately, due to large neutron deficit and strong fission competition the nuclei in this region are difficult to study experimentally. Only recently has detailed information on the deformed shapes in Bi and Po nuclei in this region started to emerge, both from in-beam and particle decay studies, see examples in Refs. [2–6] and extensive references therein.

In contrast to this, there exist only scarce data on shape coexistence in the very neutron-deficient At isotopes which is partly explained by their even higher fissility. Presently available in-beam techniques allow reliable studies of nuclei with production cross sections down to only a few hundred picobarns. Relevant examples in the region of our interest are the recent \(\alpha\) and \(\alpha\-\gamma\) study of \(^{195}\text{At}\) [12] and identification of the new \(\alpha\) emitters \(^{191}\text{At}\) and \(^{193}\text{At}\) [13], produced at the RITU gas-filled separator [14] with cross sections of about 300 pb and 40 nb, respectively.

It is well known that the ground state of the odd-mass At isotopes with \(A \geq 197\) has spin-parity \(I^+ = 9/2^-\) and is interpreted as a nearly spherical \(\pi h_{9/2}^3\) configuration. One of the important conclusions of Refs. [12,13] was that the \(1/2^+\) state, which is understood as the intruder \(\pi 3s_{1/2} \otimes \pi h_{9/2}^3\) configuration in the spherical shell model, becomes the ground state in \(^{191,193,195}\text{At}\), with no evidence for the spherical \(9/2^-\) state observed so far in these nuclei. In the deformed mean field approach this configuration corresponds to the occupation of the \(1/2^+\) [440]3s_{1/2} Nilsson orbital. The occurrence of a deformed ground state in the light At isotopes is in an agreement with theoretical calculations [1], although the change of configuration was predicted to happen already between \(^{195}\text{At}\) and \(^{193}\text{At}\).

In order to study the odd-odd isotopes it is necessary to use isomeric states with high magnetic moments. However, such investigations are notoriously difficult due to the occurrence of proton-neutron \((p-n)\) multiplets, which often result in isomeric states

\(\delta_Z\) [11], conclusions can be drawn on the structure and configuration of the states connected by the decay. One of the advantages of this method is that much higher beam intensities up to a few \(\mu\text{A}\) can be used. Combined with efficient recoil separators and modern detection systems which are used at the focal plane, this allows detailed spectroscopic studies at a cross section level down to a few hundred picobarns. Relevant examples in the region of our interest are the recent \(\alpha\) and \(\alpha\-\gamma\) study of \(^{195}\text{At}\) [12] and identification of the new \(\alpha\) emitters \(^{191}\text{At}\) and \(^{193}\text{At}\) [13], produced at the RITU gas-filled separator [14] with cross sections of about 300 pb and 40 nb, respectively.

The study of odd-odd isotopes can shed extra light on the shape coexistence phenomena. However, such investigations are notoriously difficult due to the occurrence of proton-neutron \((p-n)\) multiplets, which often result in isomeric states
and in a complex decay path of the isotopes of interest [15,16]. As a recent example of such work we refer to our detailed \( \alpha \)-decay studies of the odd-odd \( ^{184,186,188,190}\)Bi isotopes [17,18], for which complex decay schemes involving \( p-n \) multiplet states were discussed.

In this work we report on the identification of isomeric states in the new isotope \( ^{192}\)At and on their detailed \( \alpha \) and \( \alpha-\gamma \) spectroscopy. It is necessary to note that in study [13], dealing with the identification of \( ^{191,193}\)At, a brief comment on the identification of \( ^{192}\)At was made, but no data on the half-life, \( \alpha \) decay energy or decay scheme were given.

II. EXPERIMENTAL SETUP

The nucleus \( ^{192}\)At was produced by evaporation of three neutrons in the complete fusion reaction of \( ^{51}\)V ions with a \( ^{144}\)Sm target. A pulsed \( ^{51}\)V beam (5 ms on/15 ms off) with a typical intensity of about 150–200 pA on target was provided by the UNILAC heavy ion accelerator of the GSI (Darmstadt, Germany). Eight 400 \( \mu \)g/cm\(^2\) thick \( ^{144}\)Sm targets were mounted on a target wheel, rotating synchronously with the UNILAC macropulsing. The targets were produced by evaporating \( ^{144}\)SmF\(_3\) material (96.47\% isotopic enrichment) onto a carbon backing of 40 \( \mu \)g/cm\(^2\) thickness and covered with a 10 \( \mu \)g/cm\(^2\) carbon layer to increase the radiative cooling and reduce the sputtering of the material. A beam energy of \( E(\text{\textit{V}}) = 230(1) \text{ MeV} \) in the middle of the target was used, which corresponds to the maximum of the excitation function for this nuclide calculated with the statistical model code HIVAP [19].

After separation by the velocity filter SHIP [20] the evaporation residues (EVRs) were implanted into a 300 \( \mu \)m thick, 35 \times 80 \text{mm}^2 16-strip position-sensitive silicon detector (PSSD), where their subsequent particle decays were measured [21]. The \( \alpha \)-energy calibration of the PSSD was performed by using \( E_\alpha = 7167(4) \) decay of \( ^{208}\)Po [5] (\( p2n \) channel of the studied reaction, Fig. 1(a) and the \( \alpha \) lines at 5863(2) keV \( ^{209}\)Po), 6412(2) keV \( ^{208}\)At and 6643(3) keV \( ^{199}\)At) [22]. The three latter nuclides were abundantly produced in reactions with the admixtures of heavier Sm isotopes in the target. In this experiment eight strips of the PSSD had an energy resolution of \( \sim 25 \text{ keV (FWHM)} \) for the \( \alpha \) line of \( ^{192}\)Po, while for the remaining 8 strips the energy resolution was in the range of 45–75 keV. For most of the data analysis this did not cause any problems and we used the data from all 16 strips; for example, the energy resolution of the \( ^{192}\)Po peak in Fig. 1(a) is 35 keV (FWHM). However, in a few cases when the good energy resolution could be important, representative spectra from the eight strips were checked, see examples below.

Upstream of the PSSD, six silicon detectors having the same dimensions (called further “BOX detectors”) were mounted in an open box geometry, see details in Ref. [23]. They were used to measure the energies of the particles (\( \alpha \), \( \beta \) and conversion electrons), escaping from the PSSD in the backward direction.

Three thin time-of-flight (TOF) detectors [24] were installed in front of the BOX+PSSD system allowing the reaction products to be distinguished from scattered beam particles. More importantly, decay events in the PSSD could be distinguished from the implantation events by requiring an anticoincidence condition between the signals from the PSSD and from at least one of the TOF detectors.

An additional 300 \( \mu \)m thick silicon detector similar in shape to the PSSD was installed 8 mm behind the PSSD. It was used to register the energy-loss signals of the high-energy protons and \( \alpha \) particles produced in reactions on the carbon backing of the target and on the carbon charge equilibration foil installed a few cm downstream from the target. Such particles can pass through SHIP undeflected and they are not efficiently registered by the TOF detectors. Therefore, after punching through the PSSD with an energy loss of a few MeV, they create a background in the region of the \( \alpha \) particles from the decay of studied nuclei. By requiring an anticoincidence between the signals from this “veto” detector and from the PSSD detector,
a clear distinction between the decays and punch-through events can be made.

A large-volume four-fold segmented Clover germanium detector was installed behind the PSSD to measure the energies of γ rays detected within 5 μs of the detection of an EVR or α particle in the PSSD. The energy threshold for this detector was at ~20 keV, which is above the energies of the possible L x rays of the Bi and At nuclei of interest. The absolute efficiency calibration for this detector is described in Ref. [25].

III. EXPERIMENTAL RESULTS

A. Identification of two isomeric states in 192At

Figure 1(a) shows a part of the α spectrum registered in all 16 strips of the PSSD in anticoincidence with the signals from the TOF and “veto” detectors within time and position windows of 400 ms and 0.5 mm, respectively, after recoil implantation (events of the EVR-α1 type). The $E_{α1}-E_{γ}$ spectrum of α events in coincidence with γ rays is given in Fig. (1b), in which in addition to Tl and Bi K x rays a number of γ rays can be seen, e.g., at 36(1) keV, 117(1) keV, 149(1) keV and 165(1) keV. The α(6995 keV)-γ(117 keV) and α(17075 keV)-γ(149 keV) coincidence decays originate from $^{188}$Bi [17] and $^{192}$At [12], respectively; other decays will be discussed below. Figure 1(c) shows the same spectrum as in Fig. 1(a), but with an additional condition that the recoil-α1 pair must be followed by the α2 decay within time and position windows of $ΔT(α1-α2) \leq 1$ s and $ΔX(α1-α2) \leq 0.4$ mm, respectively (events of the EVR-[α1-α2] type). The strongly reduced intensity of the majority of activities in Fig. 1(c) in comparison with Fig. 1(a) is due to small α-branching ratios of respective daughter products and/or their longer half-life values in comparison with the time interval used in the α1-α2 correlation analysis. The two-dimensional $E_{α1}-E_{α2}$ spectrum corresponding to Fig. 1(c) is shown in Fig. 1(d). Due to the high intensity in Fig. 1(a) and relatively long search interval $ΔT(α1-α2)$, some of the true recoil-α1 correlated decays (e.g., from $^{192}$Po) occur in random correlations with α decays from other activities, which explains their presence in Figs. 1(c), (d). A few groups of correlated events with the energy $E_{α1} ≥ 780$ keV are present in Fig. 1(d) in the regions marked by the rectangles ’A,’ ’B,’ and ’C.’

An important comment on the α1-decay intensity in Figs. 1(c), (d) (EVR-[α1-α2] analysis) should be made here, which also applies to a number of spectra discussed below. Due to the ~50% probability of α particles to escape from the PSSD in the backward direction, the α1-α2 correlation analysis reduces the number of true correlated α events in these spectra by a factor of two in comparison with Fig. 1(a) (EVR-α1 analysis). A similar loss of intensity also happens in the EVR-[α1-γ]-α2 analysis in comparison with the EVR-[α1-γ] analysis. However, the correlation with the known α decays of the daughter nuclei provides a unique identification of the parent isotopes, which in most cases outweighs the intensity reduction.

The measured half-life $T_{1/2} = 280(20)$ ms and energy $E_{α2} = 6815(10)$ keV for the α2 decays in region ’A’ of Fig. 1(d) are in a good agreement with the decay properties of the $^{150}$I $→ (10^{-})$ α-decaying isomeric state in $^{188}$Bi ($T_{1/2} = 265(10)$ ms, $E_{α} = 6813(5)$ keV [17], see also Fig. 7 of this paper). A weaker group in the rectangle ’C’ at $E_{α2} = 7305(15)$ keV corresponds to the 7302(5) keV decay branch from the (10−) isomer with an intensity of $I_{α2} = 3.6(10)$% relative to the 6813 keV decay [17].

Similarly, the measured half-life $T_{1/2} = 66(6)$ ms and energy $E_{α2} = 6995(10)$ keV for the strongest group of the α2 decays in the rectangle ’B’ of Fig. 1(d) are in a good agreement with decay properties of the (3+) isomeric state in $^{188}$Bi ($T_{1/2} = 60(3)$ ms, $E_{α} = 6992(5)$ keV [17] and Fig. 7 of this work). The assignment of the 6995 keV decay to this isomer is also confirmed by the observation of the α2(6995 keV)-γ(117 keV) coincidences expected for this decay, see Fig. 1(b) and Ref. [17]. As discussed in detail in Ref. [17], α + e− summing in the PSSD of the energies of the α(6992 keV) decay and ~30 keV prompt electrons resulting from the K-shell internal conversion of the 117 keV E1 transition leads to the higher-energy shoulder of the 6992 keV peak, which is also seen in our data. A weaker group at $E_{α2} = 7110(15)$ keV in the rectangle ’B’ corresponds to the 7106(5) keV decay branch of the (3+) isomer with an intensity of $I_{α2} = 2.1(2)$% relative to the 6992 keV line [17].

Based on the observed EVR-[α1-α2($^{188}$Bi$^{m1,2}$)] correlations, the α1-events inside three regions ’A’, ’B’, and ’C’ of Fig. 1(d) are attributed to the decay of $^{192}$At to two α-decaying isomeric states in the daughter $^{188}$Bi nucleus. In this work we will follow the abbreviations of our study [17] in which the longer-lived $^{188}$Bi were denoted as $^{188}$Bi$^{m1}$ and $^{188}$Bi$^{m2}$, respectively. For the sake of clarity we will not use the brackets for all $F^{*}$ values in the following text, as all the spin and parity assignments mentioned in this work for $^{191,192,193}$At and their respective daughters $^{187,188,189}$Bi are tentative. However, all the tentative $F^{*}$ values will be given in brackets in Fig. 7 and in Tables I and II.

One further comment on the quoted $F^{*}$ assignments in $^{188}$Bi should be made here. As stressed in Section 4.3 of Ref. [17], while the $F^{*} = 10^{-}$ assignment for $^{188}$Bi$^{m1}$ is well established by available experimental systematics, the 3+ assignment for $^{188}$Bi$^{m2}$ is much less certain. This is because there is a clear deviation for $^{188}$Bi$^{m2}$ and its daughter $^{184}$Tl$^{m2}$ in comparison with the systematics of the low-spin states in the heavier odd-odd $^{190}$–$^{196}$Bi and $^{186}$–$^{192}$Tl isotopes (see Section 4.3.2 of Ref. [17] for details). Such a behavior may indicate a change in configuration of $^{188}$Bi$^{m2}$ or in its daughter $^{184}$Tl$^{m2}$ or in both of them. While the actual $F^{*}$ assignment for $^{188}$Bi$^{m2}$ is not important for the identification of $^{192}$At$^{m2}$ in this section, it may be crucial for the construction of its decay scheme, see discussion in Sec. IV.

Figures 2(a) and 2(b) show the time distributions $ΔT$ (EVR-[α1-α2]) between the recoil implantation and a pair of subsequent correlated α1-α2 decays for the events from the regions ‘A’ and ‘B’ of Fig. 1(d), respectively. The time distribution in Fig. 2(a) can be fitted with a single exponential function with the half-life value of $T_{1/2} = 88(6)$ ms, while Fig. 2(b) demonstrates two components with different half-lives. By using a simultaneous fit with two exponential functions shown by the dashed lines in Fig. 2(b), a good description of the
on systematics and observed in $^{192}$At and in $^{188}$Bi. The configurations based on the deduced $\tau_0$ values of $^{192}$At yield $\frac{3}{2}^-$, $\frac{5}{2}^-$, and $\frac{3}{2}^+$ isomers in $^{192}$At which decays to $^{188}$Bi. This suggests that both components originate from the same isomer in $^{192}$At which decays to both $^{188}$Bi$^{\alpha}$ and $^{188}$Bi$^{\beta}$, see text. The values of $85(10)$ ms from Fig. 2(b) and that of $88(6)$ ms from Fig. 2(a) can be considered as equal within the experimental uncertainty.

Thus, two different half-life values for decays attributed to $^{192}$At identify two $\alpha$-decaying isomeric states in this nucleus. The $88(6)$ ms isomer decaying to both $^{188}$Bi$^{\alpha,\beta}$ will further be denoted as $^{192}$At$^{\alpha}$ (events in ‘A’ and the $85(10)$ ms component in Fig. 2(a)) and $^{192}$At$^{\beta}$ (the shorter-lived component from ‘B’ of Fig. 1(d)).

The $\alpha$ and $\alpha$-$\gamma$ energy spectra for events from the regions ‘A’ and ‘B’ of Fig. 1(d) were used to establish the decay paths of $^{192}$At$^{\alpha,\beta}$. Figures 3(a)–(c) show the $\alpha$ and $\alpha$-$\gamma$ energy spectra of the $^{192}$At$^{\alpha} \rightarrow ^{188}$Bi$^{\alpha}$ decays from the region ‘A’, while Figs. 4(a)–(c) and Figs. 5(a)–(c) provide the corresponding spectra from the region ‘B’ with

### Table I. The measured decay properties of $^{192}$At. Shown are isomer assignments, $\alpha$-decay energies $E_\alpha$, relative intensities $I_\alpha$, reduced $\alpha$ widths $\delta_\alpha$, hindrance factors $HF$ and energies and multipolarities of coincident $\gamma$ rays. The $\gamma$-ray energy uncertainty is 1 keV. The reduced $\alpha$ widths were calculated with the Rasmussen prescription [11] by assuming $\Delta L = 0$ decays. The $HF$ values were calculated relative to the average value of $\delta_\alpha = 58(7)$ keV for unhindered $7/2^- \rightarrow 7/2^-$ $\alpha$ decays in $^{191,193,195}$At [12,13].

full decay curve could be obtained with the half-life values of $T_{1/2} = 11.5(6)$ ms and $T_{1/2} = 85(10)$ ms for the shorter-lived and longer-lived components, respectively. The values of $85(10)$ ms from Fig. 2(b) and that of $88(6)$ ms from Fig. 2(a) can be considered as equal within the experimental uncertainty. The values of $85(10)$ ms from Fig. 2(b) and that of $88(6)$ ms from Fig. 2(a) can be considered as equal within the experimental uncertainty. This suggests that both components originate from the same isomer in $^{192}$At which decays to both $^{188}$Bi$^{\alpha}$ (see Sec. III B) and to $^{188}$Bi$^{\beta}$ (see Sec. III D). The ratio of the intensity of the $88$ ms component in Fig. 2(a) to that in Fig. 2(b) is 1.6(1).

Thus, two different half-life values for decays attributed to $^{192}$At identify two $\alpha$-decaying isomeric states in this nucleus. The $88(6)$ ms isomer decaying to both $^{188}$Bi$^{\alpha,\beta}$ will further be denoted as $^{192}$At$^{\alpha}$ (events in ‘A’ and the $85(10)$ ms component in ‘B’ of Fig. 1(d)), while the $11.5(6)$ ms isomer decaying to $^{188}$Bi$^{\beta}$ will be denoted as $^{192}$At$^{\beta}$ (the shorter-lived component from ‘B’ of Fig. 1(d)).

The $\alpha$ and $\alpha$-$\gamma$ energy spectra for events from the regions ‘A’ and ‘B’ of Fig. 1(d) were used to establish the decay paths of $^{192}$At$^{\alpha,\beta}$. Figures 3(a)–(c) show the $\alpha$ and $\alpha$-$\gamma$ energy spectra of the $^{192}$At$^{\alpha}$ $\rightarrow ^{188}$Bi$^{\alpha}$ decays from the region ‘A’, while Figs. 4(a)–(c) and Figs. 5(a)–(c) provide the corresponding spectra from the region ‘B’ with

### Table II. Main configurations and $F^0$ assignments expected and observed in $^{192}$At and in $^{188}$Bi. The configurations based on the $\pi 3f_{1/2}, \pi 2p_{1/2}, \pi 1f_{1/2}$, and $\pi 1i_{13/2}$ protons are the same in both nuclei. The deduced $F^0$ assignments in column 3 are tentative and based on systematics and $\alpha$-decay data, such as $HF$ values and decay characteristics.

$^a$Only one state from this multiplet was observed in $^{192}$At$^{\alpha}$ and in $^{188}$Bi$^{\alpha}$ (at 165 keV); based on the available data both assignments are possible, see text.

$^b$Observed in $^{188}$Bi.
conditions $\Delta T(\text{EVR-} \alpha_1) \leq 30 \text{ ms}$ and $\Delta T(\text{EVR-} \alpha_1) = 70-400 \text{ ms}$, respectively. The latter conditions were chosen with the aim to highlight the $^{192}\text{At}^{m1} \rightarrow ^{188}\text{Bi}^{m2}$ and $^{192}\text{At}^{m1} \rightarrow ^{188}\text{Bi}^{m2}$ decays, respectively, by minimizing the contribution of the $T_{1/2} = 11.5 \text{ ms}$ isomer to the $\alpha_1$ spectrum of the $T_{1/2} = 88 \text{ ms}$ isomer and vice versa, while keeping the number of counts in both spectra high enough for subsequent $\alpha_1-\gamma$ analysis (Fig. 6). To account for the 60 ms half-life of $^{188}\text{Bi}^{m2}$ a condition $\Delta T(\alpha_1-\gamma) \leq 240 \text{ ms}$ was also applied to produce Figs. 4(a) and 5(a).

With the aim to show the full $\gamma$-ray intensity following the decay of $^{192}\text{At}$, Fig. 6(a) shows a part of the $\gamma$-ray spectrum in coincidence with the $E_{\alpha_1} \geq 7180 \text{ keV}$ decays from Figs. 1(b) (events of the type EVR-[$\alpha_1-\gamma$] above the $\alpha_1$ decay of $^{192}\text{Po}$). In the spectrum, in addition to the Bi K x rays, a few $\gamma$ lines are seen, e.g., at 27(1) keV (8 events), 36(1) keV (74 events), broad structure denoted as 64(3) keV (30 events), 101 keV (15 events), 165 keV (41 events) and 188(1) (nine events). No statistically significant $\gamma$ lines were observed above $E_\gamma = 200 \text{ keV}$. As will be discussed below, most of these $\gamma$ transitions originate from the excited states in $^{188}\text{Bi}$ fed by fine-structure $\alpha$ decays of $^{192}\text{At}$.

The production cross section of $^{192}\text{At}$ was estimated as $\sigma = 40(10) \text{ nb}$ by using the calculated SHIP efficiency of 40% [20,21].

B. $^{192}\text{At}^{m1} \rightarrow ^{188}\text{Bi}^{m1}$ decay

$\alpha$ peaks at 7224(15) keV, 7305(15) keV, 7385(15) keV and, possibly, at 7195(15) keV can be distinguished in Fig. 3(a). The broadening of the $7224 \text{ keV}$ peak is due to the $\alpha_1-\text{e}^- \gamma$ summing in the PSSD as discussed below. It is important to note that the same peaks are also seen in the spectrum registered in the eight strips of the PSSD with the best energy resolution (solid histogram in Fig. 3(a)).

Figure 3(b) shows the $\alpha_1$ decays registered in coincidence with the $E_\gamma \leq 250 \text{ keV}$ $\gamma$ rays, while the corresponding two-dimensional $E_{\alpha_1}-E_\gamma$ spectrum and its projection on the $E_\gamma$ axis are shown in Fig. 3(c) and Fig. 6(b), respectively. The $\alpha_1(7224 \text{ keV})-\gamma(165 \text{ keV})$ coincidences in Fig. 3(c) identify the fine structure $E_\alpha = 7224 \text{ keV}$ decay of $^{192}\text{At}^{m1}$ and the $E* = 165 \text{ keV}$ excited state in $^{188}\text{Bi}^{m1}$ (see Fig. 7). Based on the similar total $Q_\alpha$ values for the $\alpha_1(7224 \text{ keV})-\gamma(165 \text{ keV})$ transitions...
events and for the 7385(15) keV decay in Fig. 3(a), the latter decay is assigned as the full energy 'cross-over' transition to the 10− state in 188Bi[41], see Fig. 7.

The peak at 7305(15) keV in Figs. 3(a) and 3(b) is then understood as resulting from the full $\alpha + e^-$ summing in the PSSD of the energies of the 7224 keV decays and electrons of $E_e = E_\gamma(165 \text{ keV}) - E_K(\text{Bi}) = 74.5 \text{ keV}$ originating from the K-shell internal conversion of the 165 keV transition, ($E_K(\text{Bi}) = 90.5 \text{ keV}$ is the Bi K-shell electron binding energy [22]). Partial summing with the electrons escaping from the PSSD explains the higher-energy tail of the 7224 keV decay denoted as $\alpha + e^-$ in Fig. 3(b) and extending up to the full-energy summing peak at 7305(15) keV. This is also confirmed by the coincidences of the $\alpha + e^-$ events at $E_\gamma = 7230$–7320 keV with the Bi K x rays, see Fig. 3(c). Furthermore, the $\alpha + e^-$ summing with the $L_{1,3}$-shell electrons ($E_{e,L} \sim 150 \text{ keV}$, as $B_{L_{1,3}}(\text{Bi}) = 13.4$–16.4 keV) will contribute, though with less intensity, to the energy region between the 7224 keV and 7385 keV peaks in Fig. 3(a). These inferences were confirmed by the GEANT Monte-Carlo simulations with the dedicated code developed for the SHIP detection system [23]. The simulations included the summing effects with the electrons and x rays from the K- and L-shell internal conversion of the 165 keV transition and also implemented different energy resolution of the PSSD’s strips as observed in the experiment. Note that as the energy threshold in the Clover detector was at $\sim 20 \text{ keV}$, which is above the energy of the Bi L x rays, no $\alpha$-L x rays events are seen in our spectra.

By comparing the numbers of the full-energy $\alpha(7224 \text{ keV})\gamma(165 \text{ keV})$ coincident events and $\alpha(7230$–7320 keV)-Bi K x rays events from Fig. 3(c) (after normalization with the corresponding $\gamma$-ray detection efficiencies) a K-conversion coefficient of $\alpha_K(E) = 3(1)$ was deduced. This establishes a $M1$ multipolarity for the 165 keV $\gamma$ ray, as the theoretical conversion coefficients are $\alpha_K(E1) = 0.1$, $\alpha_K(E2) = 0.25$, $\alpha_K(M1) = 2.1$, $\alpha_K(M2) = 9.77$ [26].

The higher-energy tail of the peak at 7385 keV in the open histogram in Fig. 3(a) practically disappears in the spectrum corresponding to the eight strips with the best energy resolution (Fig. 3(a), solid histogram). Therefore, we assume that these events are due to the strips with the poorer energy resolution. This is in agreement with the GEANT simulations which indeed show the tail above the 7385 keV.

In contrast to this, the group at 7195(15) keV is present in both spectra in Fig. 3(a). Some of these decays are in
coincidence with 165 keV γ decays (three events) and Bi K x rays (Fig. 3(c)). Based on the Qα analysis, this α decay establishes an excited state at 190(15) keV in 188Bi\textsuperscript{m1} with one of the deexcitation paths to the long-lived 10\textsuperscript{−} state proceeding via a cascade of 165(1) keV M1 and yet unobserved low-energy Eγ = 25(15) keV transitions. A single coincident 7203(15) keV-188(1) keV event in Fig. 3(c) is tentatively considered as evidence for the direct γ decay from this state to the 10\textsuperscript{−} state, which would determine the excitation energy of this state as E* = 188(1) keV.

The 64 keV γ transition (four counts, Figs. 3(c) and 6(b)) was observed in coincidence with broadly distributed α decays at Eα \sim 7200–7360 keV. As three of the four counts at 64 keV are in coincidence with the 7224 keV decay (Fig. 3(c)), we assume the existence of a cascade consisting of 64 keV and yet unobserved 101 keV transitions, which form the second deexcitation path from the state at 165 keV in 188Bi\textsuperscript{m1} (not shown in Fig. 7). The order of the transitions cannot be established from our data. Both transitions will most probably be partially converted, resulting in a cascade of the electrons which will additionally contribute to the α + e\textsuperscript{−} summing in the region between 7224 keV and 7385 keV peaks in Fig. 3(a).

The tentative cross-over 192At\textsuperscript{m1} \rightarrow 188Bi\textsuperscript{m2} decay at 7510–7560 keV will be discussed in Sec. III D, in which also the evidence for the strongly-converted decay(s) from the state at 165 keV to states resulting from the proton-neutron multiplets (denoted by the ‘p-n’ in Fig. 7) in 188Bi is presented.

The data for 192At\textsuperscript{m1} are summarized in Table I and will be discussed in Sec. IV.

C. 192At\textsuperscript{m2} \rightarrow 188Bi\textsuperscript{m2} decay

To highlight the 11.5 ms decays of 192At, Fig. 4(a) shows the α\textsuperspectrum from the rectangle ‘B’ of Fig. 1(d) for the time intervals of ΔT(EVR-α1) \leq 30 ms and ΔT(α1-α2) \leq 240 ms. A weak peak at 7363(15) keV along with two broader structures at \sim 7410–7480 keV and 7510–7560 keV are seen in Fig. 4(a), thus they must be attributed to the decay of 192At\textsuperscript{m2}.

FIG. 7. Proposed decay schemes of 192At\textsuperscript{m1, m2}. The decay schemes of the daughter isotopes 188Bi\textsuperscript{m1, m2} were taken from Ref. [17]. The HF values are relative to the hindrance factor for the unhindered decay in each isomer, for which a normalized value of HF = 1 was adopted for this figure. The actual HF values relative to unhindered α decays in the neighbors 191,193,195At are shown in Table I. The 7510–7560 keV decays, shown by the dashed lines, do exist in both isomers (see Table I), but their placement is uncertain (see text). The simplified partial decay scheme of 193At was taken from Ref. [13]. All F\textsuperscript{+} assignments are tentative and based on the α decay pattern and systematics, see Refs. [13,17].
The $\alpha$1 decays from Fig. 4(a) in coincidence with $E_{\gamma} \leq 250$ keV $\gamma$ decays are shown in Fig. 4(b), while the corresponding two-dimensional $E_{\alpha1}-E_{\gamma}$ spectrum and its projection on the $E_{\alpha}$ axis are given in Figs. 4(c) and 6(c), respectively. In addition to the 7363 keV peak, an $\alpha$ line at 7435(15) keV can be seen in Fig. 4(b). A weaker group at $\sim$7405(20) keV results most probably from the $\alpha + e^{-}$ summing as discussed below. Figure 4(c) shows that the 7435 keV decay is in coincidence with a 36 keV $\gamma$ decay, being the strongest $\gamma$ transition following the $\alpha$ decay of $^{192}$At (Fig. 6(c)). The total value $Q_{\alpha,\text{total}} = Q_{\alpha}(7435\text{ keV}) + E_{\gamma}(36\text{ keV})$ is equal within the experimental uncertainty to the $Q_{\alpha}$ value of the 7470 keV decay in Fig. 4(a). On this basis we assign the 7470(15) keV decay as the full-energy crossover transition to the state in $^{188}$Bi from the 7470 keV peak, which explains the broad structure at 7410–7480 keV results from Fig. 1(b) is shown in Fig. 4(d) (EVR-$\alpha$). The 36 keV transition must be at least partially converted to the 7470 keV peak, which deexcites both by a partially $M1$ (after normalization on the corresponding $\gamma$ spectrum and its projection in the PSSD, along with the short summing with subsequent $L$- and $M$- shell conversion (e.g., $\alpha_{\text{tot, calc.}}(E1) = 1.5$, $\alpha_{\text{tot, calc.}}(M1) = 41$ [26]), resulting in conversion electrons with the energy of $E_{\gamma} \sim 20$ keV ($L$-shell conversion) or $E_{\gamma} \sim 33$ keV ($M$-shell conversion). The $\alpha(7435\text{ keV}) + e^{-}(L,M)$ energy summing in the PSSD, along with the long summing with subsequent $L$- and $M$- shell conversion, broadens the 7435 keV peak toward the higher energy, up to the 7470 keV peak, which explains the broad structure at 7410–7480 keV in Fig. 4(a). Based on the observed number of the $\alpha(7435\text{ keV})-\gamma(36\text{ keV})$ coincident events in Fig. 4(c) (after normalization on the corresponding $\gamma$-ray efficiency), an $M1$ or any higher multipolarity for the 36 keV transition must be ruled out, as otherwise the calculated intensity of the $\alpha + e^{-}$ summing peak alone would be by more than one order of magnitude stronger compared to the observed intensity of the whole 7410–7480 keV group. Therefore, an $E1$ multipolarity was assigned to the 36 keV transition.

It is important to note at this stage that the 36 keV transition also arises in the $^{192}$At$^{m2} \rightarrow ^{188}$Bi$^{m2}$ decay branch (to be discussed in detail in the next section). This is confirmed by Fig. 2(d), which shows the time distribution between the recoil and subsequent pair of coincident $\alpha1-\gamma$ events from the region denoted by the rectangle in Fig. 1(b). A shorter-lived $T_{1/2} = 9(3)\text{ ms}$ and a longer-lived $T_{1/2} = 100(30)\text{ ms}$ components are seen in Fig. 2(d), their half-lives being consistent within the experimental uncertainty with the half-life values of $^{192}$At$^{m2}$ and $^{192}$At$^{m1}$, respectively.

The $\alpha$1 spectrum in coincidence with the 36 keV $\gamma$ rays from Fig. 1(b) is shown in Fig. 4(d) (EVR-$\alpha-\gamma(36\text{ keV})$ analysis). Figures 4(c), (d), prove that the 7363 keV decay is seen in coincidence with both $\alpha$ K X rays and 36 keV decays. This means that the 7363 keV decay feeds to an excited state in $^{188}$Bi, which deexcites both by a partially converted $E_{\gamma} < B_{K}(\alpha B_{K}) = 90.5$ keV transition and by a cascade of transitions involving the 36 keV $E1$ decay. Based on the $Q_{\alpha}$ energy balance for the 7363(15) keV and 7470(15) keV decays, a still unobserved $E_{\gamma}(107(15)\text{ keV})$ decay could be a candidate for the former transition, which would define the energy of 71(15) keV for the $\gamma$ ray being in cascade with the 36 keV transition. The $K$-shell conversion of the 107 keV decay would naturally explain the observed 7363 keV-$\alpha$ K X rays coincidences. Additionally, the $\alpha(7363\text{ keV}) + e^{-}$ summing with the $L$- and $M$- shell conversion electrons from the coincident 36 keV $E1$ decay and yet unobserved 107 keV and 71 keV transition would then result in the higher-energy tail of the 7363 keV line extending nearly up to the 7470 keV decay.

The 36 keV transition is also seen in Figs. 4(c), (d) in coincidence with the extended region of $\alpha$ decays at 7200–7350 keV, which signifies the presence of other weaker yet unobserved fine-structure decays in $^{192}$At$^{m1,m2}$, which feed to excited states whose de-excitation paths include the 36 keV $E1$ transition.

The highest-energy group at $E_{\alpha1} = 7510–7560$ keV appears in Fig. 4(a) both for all 16 strips (open histogram) and for eight strips with the best energy resolution (solid histogram). The same structure is also seen in Figs. 1(a)–(d). The time distribution for these events, deduced from the recoil-$\alpha$ analysis (Fig. 2(c)), demonstrates two components with half-lives of $T_{1/2} = 9(2)\text{ ms}$ and $T_{1/2} = 95(30)\text{ ms}$, which match within the experimental uncertainties the half-lives of $^{192}$At$^{m2}$ and of $^{192}$At$^{m1}$, respectively (cf. also to Fig. 2(d)). From Fig. 2(c) we estimate that within a time interval of $\Delta T(EVR-\alpha) \lesssim 30\text{ ms}$ approximately two-thirds of the counts in the 7510–7560 keV group originate from $^{192}$At$^{m2}$ (11.5 ms decay), while the rest must be attributed to $^{192}$At$^{m1}$ (88 ms decay). Although we cannot separate the respective contributions within the given time interval due to the limited number of observed events, these data unambiguously prove that the highest-energy $\alpha$ decay of $^{192}$At$^{m2}$ has the energy in the range of 7510–7560 keV, see Fig. 7. From the intensity balance discussed above, an estimate of $I_{\gamma}(7510–7560\text{ keV}) \leq 1.0(5\%)$ was deduced, see Table I.

Based on the energy difference between the 7470 keV $\alpha$ decay and the group at 7510–7560 keV, one has to assume that the former decay (and, therefore, the 7435 keV-$36$ keV pair) feeds an excited isomeric state at $\Delta = 65(25)$ keV in $^{188}$Bi$^{m2}$, which deexcites by a long-lived $T_{1/2} > 5\mu$s transition, presumably to the $3^{+}$ state in $^{188}$Bi$^{m2}$ (see Fig. 7). Otherwise, if the state at 65(25) keV were not isomeric, one would expect to observe the coincidences of the 7435 keV and 7470 keV decays with the $\gamma$ ray(s) deexciting this state, which were not observed in our data. This nonobservation could be explained by the strong $L$- and $M$-shell conversion of the corresponding $\gamma$ decay, but in this case the $\alpha + e^{-}$ summing peak at an energy $E_{\gamma} \sim 7480 + 65(25)\text{ Bi}(L,M) \sim 7530(25)\text{ keV}$ would be expected with an intensity comparable to that of the whole broad peak at 7410–7480 keV. The latter inference follows from the GEANT simulations performed for this scenario. The nonobservation of such an intense structure in our data confirms the isomeric nature of the state at 65(25) keV in $^{188}$Bi. It is worth noting that in the neighboring odd-mass $^{187,189}$Bi isotopes long-lived isomeric states are known at an excitation energy below 200 keV (see Fig. 7 for $^{189}$Bi).

The deduced data and decay scheme of $^{192}$At$^{m2}$ are given in Table I and Fig. 7, respectively.

D. $^{192}$At$^{m1} \rightarrow ^{188}$Bi$^{m2}$ decay

In this section we discuss the long-lived component in Fig. 2(b) which is presumably due to the $^{192}$At$^{m1} \rightarrow ^{188}$Bi$^{m2}$ decay branch.
Figure 5(a) shows the spectrum of $\alpha$ decays from rectangle ‘B’ of Fig. 1(d) under conditions $\Delta T(EVR-\alpha_1 = 70–400$ ms and $\Delta T(\alpha_1-\alpha_2) \leq 240$ ms. The events from Fig. 5(a) in coincidence with $E_\gamma < 250$ keV $\gamma$ decays are shown in Fig. 5(b), while the corresponding two-dimensional $E_{\alpha_1}-E_\gamma$ spectrum and its projection on the $E_\gamma$ axis are given in Figs. 5(c) and 6(d), respectively.

The broad structureless $\alpha 1$ spectrum in Fig. 5(a) can only be explained by assuming that the parent $\alpha$ decay of $^{192}$At is followed by a cascade of strongly converted low-energy $\gamma$ transitions. The subsequent $\alpha + e^-$ summing in the PSSD then smears out the $\alpha 1$ decay spectrum for this component.

Based upon the $\alpha-\gamma$ data in Figs. 5(b), (c) and 6(d) and anticipating the discussion of the proton-neutron multiplet states expected in the daughter $^{188}$Bi, we propose the following scenario for the $^{192}$At$^{m1} \rightarrow ^{188}$Bi$^{m2}$ decay (see Fig. 7). Namely, in addition to the 165 keV $M1$ transition from the excited state at 165 keV decaying to the 10$^-$ state in $^{188}$Bi$^{m1}$, there should exist low-energy $\gamma$ decays to a number of low-lying closely-spaced excited states decaying to $^{188}$Bi$^{m2}$. As discussed in the next section, a multitude of such states is readily available from the coupling of the $\nu 1_{1/2}, \nu 1_{3/2}$ neutrons to the low-lying $\pi 3_{1/2}$, $\pi 1_{1/2}$ and $\pi 1_{13/2}$ proton orbitals (see Table II). Clearly, the decays from the 165 keV state to some of these states (schematically denoted by ‘$p-n$’ in Fig. 7) and subsequent low-energy intramultiplet $M1$ and/or $E2$ $\gamma$ transitions will be strongly converted, which results in the $\alpha + e^-$ summing in the PSSD. Two important observations confirm this scenario.

First of all, we note the strong presence of Bi $K$ x rays (Fig. 6(d)) and a relatively low ratio of $I_{\alpha}/I_{\gamma} \sim 3.9$ of the number of $\alpha$ decays and $\alpha-\gamma$ decays in Figs. 5(a) and 5(b), respectively. For comparison, the corresponding ratios are $I_{\alpha}/I_{\gamma} \sim 10$ for the $^{192}$At$^{m1} \rightarrow ^{188}$Bi$^{m1}$ decay (Figs. 3(a), (b)) and $I_{\alpha}/I_{\gamma} \sim 12.9$ for the $^{192}$At$^{m2} \rightarrow ^{188}$Bi$^{m2}$ decay (Figs. 4(a), (b)). Thus, on average, each $\alpha$ decay from the $^{192}$At$^{m1} \rightarrow ^{188}$Bi$^{m2}$ branch is accompanied by at least a factor of 2.5 more $\gamma$ rays and/or Bi $K$ x rays compared to the $\alpha$ decays from the $^{192}$At$^{m1} \rightarrow ^{188}$Bi$^{m1}$ and $^{192}$At$^{m2} \rightarrow ^{188}$Bi$^{m2}$ branches. Secondly, the spectrum in Fig. 5(a) starts at an energy of $\sim 7220$ keV, which corresponds to the energy of the strongest decay of $^{192}$At$^{m1}$ ($E_\alpha = 7224$ keV), feeding to the 165 keV state on these grounds we suggest the decay scheme for the $^{192}$At$^{m1} \rightarrow ^{188}$Bi$^{m2}$ branch as shown in Fig. 7.

In addition to Bi $K$ x rays, three peaks at 36(2) keV (five events), 66(1) keV (seven events) and 101(1) keV (three events) are seen in Fig. 6(d). All of them are in coincidence with the broadly-distributed $\alpha 1$ decays of $^{192}$At$^{m1}$ as shown in Fig. 5(c), thus the $\alpha + e^-$ summing is also important in these cases. Due to the low number of counts and broad energy distribution the coincidence $\alpha$ decays the placement of these $\gamma$ rays was not possible.

We will only consider the 36(2) keV decay seen in coincidence with the broadly-distributed $\alpha$ decays at 7250–7410 keV in Fig. 5(c). This group cannot be due to the contribution from the 36 keV $\gamma$ ray originating after decay of $^{192}$At$^{m2}$. This is confirmed by the time distribution $\Delta T(EVR-\alpha 1-\gamma(36$ keV)) events in Fig. 2(d), which shows the two components for the feeding coincident $\alpha$ decays. By using the exponential decay formula, a value of $I_{\alpha}(0–30$ ms)/$I_{\alpha}(70–400$ ms) $\sim 67$ can be estimated for the ratio of the number of decays in the 0–30 ms and 70–400 ms time intervals for the 11.5 ms $\alpha$ decay. Therefore, starting from 25 decays at 36 keV observed for the 11.5 ms component in Fig. 6(c) and by applying the above ratio, at most 0.37 counts at 36 keV can be expected in Fig. 6(d) due to the 11.5 ms component, while experimentally we observed five counts.

The spectrum of $\alpha 1$ decays in coincidence with the 36 keV transition from the EVR-[$\alpha 1-\gamma(36$ keV)] analysis ($\Delta T(EVR-\alpha 1) = 70–400$ ms) is shown in Fig. 5(d). The spectrum structure is clearly different compared to Fig. 4(d) which shows the corresponding analysis for $^{192}$Am$^{m2}$. Above data prove unambiguously that $^{192}$At$^{m1}$ feeds to an excited state in $^{188}$Bi decaying further by the 36 keV transition, but no conclusion can be drawn on whether this state and the state fed by the 7435 keV of $^{192}$Am$^{m2}$ are the same.

Finally, we discuss the group of 26 events at $E_{\alpha 1} = 7510–7560$ keV in Fig. 5(a). Such a structure (14 counts) is also present in the spectrum, corresponding to the detectors with the best energy resolution (not shown for the sake of clarity of Fig. 5(a)). Presently this decay is tentatively shown in Fig. 7 as directly feeding to the $3^+$ state in $^{188}$Bi. However, two of these decays are in coincidence with the Bi $K$ x rays (Figs. 5(c), (d)), which may indicate that this decay feeds to an excited state in $^{188}$Bi which further decays by a partially $K$-shell converted transition to the $3^+$ state. The resulting $\alpha + e^-$ summing would explain the broad energy distribution of this group.

In principle, a rough estimate of the relative position of two isomers in $^{192}$At (and, therefore, in $^{188}$Bi and $^{184}$Tl) could be obtained based on observation of this transition. However, due to the placement and energy uncertainty discussed above we prefer not to deduce any definite values here.

IV. DISCUSSION

Spectroscopic studies of the odd-odd At and Bi isotopes are difficult due to a variety of closely-lying configurations expected in these nuclei. The recent $\alpha$-decay studies of the odd-proton isotopes $^{191,193}$At [13] are very helpful in this respect as they identified the lowest-lying proton states in the nuclei being the direct neighbors of $^{192}$At studied in this work. As an example, the partial decay scheme of $^{190}$At relevant for our discussion is shown on the right-hand side of Fig. 7. In $^{193}$At three states (1/2+, 7/2− and 13/2+) were found within 39(7) keV of each other. In $^{191}$At, no 13/2− state has yet been observed, but the decay schemes of the known 1/2+ and 7/2− states ($\Delta E^*(7/2−-4/2^−) = 50(30)$ keV [13]) are qualitatively similar to that of the corresponding states in $^{193}$At.

Therefore, in $^{192}$At one expects the lowest configurations to be due to the coupling of the $\pi 3_{1/2}$, $\pi 2_{1/2}$ and, possibly, $\pi 1_{13/2}$ neutrons to the $\nu 3_{1/2}$ and/or $\nu 1_{13/2}$ neutrons, which are known to be the lowest in the lead region in vicinity of the neutron midshell at $N = 104$. Table II summarizes the possible main configurations and $I^+$ assignments expected in $^{192}$At.

By analogy, the possible configurations in the daughter nucleus $^{188}$Bi can be understood by considering the coupling of the valence $\nu 3_{1/2}$ or $\nu 1_{13/2}$ neutron to the lowest
proton-based states in the neighboring $^{187,189}$Bi isotopes. In the latter nuclei, along with the $9/2^-$ ground state three excited states ($1/2^+, 7/2^+, 13/2^+$) were observed within 252 keV in $^{187}$Bi or 358 keV in $^{189}$Bi, see Fig. 7 for the latter case. Therefore, in $^{188}$Bi one may expect a multitude (a few tens) of low-lying states in the range of $11^0$-$0^0$,$0^+-13^+$ within the energy interval of a few hundred keV which results from the $p$-$n$ multiplets shown in Table II. Furthermore, multiple states with the same $I^+$ originating from different multiplets can be expected in $^{188}$Bi, as for example three possible $8^+$ and three $3^+$ states. Depending on their relative position, the states belonging to different $p$-$n$ multiplets in $^{188}$Bi may intermingle with each other, leading to a complex decay path between them. The previously known $10^-$ ($^{188}$Bi$m^{1}$) and $3^+$ ($^{188}$Bi$m^{2}$) $\alpha$-decaying isomeric states in $^{188}$Bi have presumably the $\pi l_{9/2} \nu v2\ i_{13/2}$ and $\pi l_{9/2} \nu v3\ s_{1/2}$ configuration, respectively (Table II and Fig. 7), though, as mentioned in Sec. III A, the latter assignment is less certain.

$\alpha$ decay is a sensitive tool to study multiplet states in the odd-odd nuclei, as it selectively connects the states with the same spin, parity and configuration. For example, in our $\alpha$-decay studies of the odd-odd $^{184-196}$Bi isotopes [15,17,18], the $\Delta L = 0 \ 10^- \rightarrow 10^-$ and $3^+ \rightarrow 3^+ \ alpha$ decays between the states of the same configuration and $F^+$ values have been observed, unhindered when compared to their even-even neighbors. As an example, the $^{188}$Bi $\rightarrow$ $^{184}$Tl $\alpha$ decay can be seen in Fig. 7. In contrast, the spin-changing $\Delta L \neq 0$ $\alpha$ decays to other states of the same multiplet/configuration were strongly hindered, such as the $10^- \rightarrow 9^-$ decays in $^{194}$Bi ($HF = 175(50)$) and in $^{192}$Bi ($HF = 41(14)$). Even higher hindrance factors were deduced for the decays with a change of configuration and $F^+$ values in these nuclei, see, for example the strongly hindered $10^- \rightarrow 6^+$ ($HF = 600(150)$) and $10^- \rightarrow 7^+$ ($HF = 1350(350)$) decays of $^{188}$Bi$m^{1}$ (Fig. 7) and extensive data for $^{184-196}$Bi isotopes in Refs. [15,17,18]. In terms of absolute intensity, practically all $\Delta L \neq 0$ $\alpha$ decays have intensities less than a few percent relative to the favored $\Delta L = 0$ decay. A similar pattern was also observed in the doubly odd $^{202,204,206}$Fr $\rightarrow$ $^{202,204,206}$At $\rightarrow$ $^{198,196,194}$Bi $\alpha$-decay chains studied in Ref. [16].

Therefore, in the decay of $^{192}$At$m^{1,m^{2}}$ a similar pattern can be expected with the strongest $\Delta L = 0$ unhindered $\alpha$ decay between the states of the same configuration and $F^+$ along with much weaker $\Delta L \neq 0$ decays.

We start the discussion with the $^{192}$At$m^{1} \rightarrow$ $^{188}$Bi$m^{1}$ branch. The hindrance factor for the 7224 keV $\alpha$ decay ($\delta_0^2 = 28(4)$ keV) in $^{192}$At$m^{1}$ relative to the unhindered $7/2^- \rightarrow 7/2^-\alpha$ decays in $^{191,193,195}$At, all of them having a comparable reduced $\alpha$ width of $\delta_0^2 \sim 55-60$ keV [12,13], is $HF = 2.1(4)$, see Table I. The slight retardation of the 7224 keV decay is most probably due to a blocking effect, as seen, for example, in the comparison of the $\alpha$ decays of the odd- and even- mass Po nuclei [28]. Apart from this hindrance, the 7224 keV decay can be considered as a favored transition, which indicates that the configurations and $F^+$ values of $^{192}$At$m^{1}$ and of the 165 keV state are the same. In contrast, the cross-over 7385 keV $\alpha$ decay is hindered by a factor of $HF = 20(4)$ relative to the 7224 keV decay (Fig. 7), thus the configurations and/or $F^+$ values of $^{192}$At$m^{1}$ and of the $10^-\alpha$-decaying state in $^{188}$Bi$m^{1}$ must be different. A similar pattern is observed in $^{191,193,195}$At, in which the full-energy crossover $7/2^- \rightarrow 9/2^-$ decays are hindered compared to unhindered $7/2^- \rightarrow 7/2^-\alpha$ decays [12,13], with the values of $HF = 47(6), 50(50)$ and 64(64) for $^{195}$At, $^{193}$At and $^{191}$At, respectively (see Fig. 7 for $^{193}$At).

Based on the assumed 10$^-$ assignment for the $\alpha$ decaying state in $^{188}$Bi$m^{1}$ and an $M1$ multipolarity for the 165 keV transition, a spin-parity of $F^+ = 9^-11^-$ is plausible for the latter state. The $F^+ = 11^-$ assignment can be ruled out, as otherwise the unhindered nature of the 7224 keV would establish the $F^+ = 11^-$ value for $^{192}$At$m^{1}$, which is not possible within configurations available for this nucleus in Table II. Therefore, only values of $F^+ = 9^- or 10^-$, both resulting from the $[\pi f_7/2 \times v1i_{13/2}]_{1-10} \ or [\pi l_{9/2} \times v3s_{1/2}]_{1-11}$ multiplet, should be considered for the 165 keV state in $^{188}$Bi$m^{1}$ and for $^{192}$At$m^{1}$. Since no unambiguous conclusion can be drawn in favor of either of them, we keep both possible assignments in Table II and Fig. 7. It is important to stress that the deduced configuration in $^{192}$At$m^{1}$ is based on the same proton $\pi 2f_{7/2}$ configuration as the $7/2^-$ isomers in the neighboring $^{191,193}$At isotopes. This indirectly supports our inferences and confirms the expected onset of deformation in the At isotopes when approaching the neutron mid-shell at $N = 104$. Similarly, the $9,10^-\ 165$ keV state in $^{188}$Bi$m^{1}$, and the $7/2^-$ excited states at 63(10) keV in $^{187}$Bi and at 99.6(5) keV in $^{195}$Bi decay by an $M1$ transition are based on the same proton configuration.

The excited state at 188(1)keV in $^{188}$Bi$m^{1}$ fed by the 7195 keV hindered decay (HF = 16(4)) relative to the 7224 keV decay could then be another member of the $[\pi 2f_{7/2} \times v1i_{13/2}]_{1-10} \ or [\pi l_{9/2} \times v3s_{1/2}]_{1-11}$ multiplets.

In contrast to $^{192}$At$m^{1}$, no configuration assignment cannot presently be made for the $^{192}$At$m^{2}$ isomer. There are a few reasons for this. First of all, as mentioned earlier, the configuration and $F^+ = 3^+$ assignment for the daughter $^{188}$Bi$m^{2}$ isomer are less certain in comparison with those of the $10^-\,^{188}$Bi$m^{1}$ isomer. Indeed, there is a clear deviation of the energy systematics for the presumable $3^+ \rightarrow 3^+$ and $3^+ \rightarrow 2^+$ decays of the low-spin isomer $^{188}$Bi$m^{2}$ in comparison with their trend in the heavier odd-odd $^{190-196}$Bi isotopes. Also, the 117 keV $E1$ transition in $^{184}$Tm$m^{2}$ does not follow the trend of the $E1$ decays in the heavier odd-odd Tl isotopes (see Fig. 8 of Ref. [17]). It is not clear if these effects are due to change of systematics in $^{188}$Bi$m^{2}$, or in $^{184}$Tm$m^{2}$, or in both of them. Therefore, in our analysis of the $^{192}$At$m^{2} \rightarrow$ $^{188}$Bi$m^{2}$ branch we cannot rely on the properties of the daughter isotope as we could in the case of $^{192}$At$m^{1}$. Furthermore, the multitude of the available closely-lying multiplet states in $^{188}$Bi$m^{2}$ results in many possible scenarios, most of which cannot be confirmed or discarded based on the available data. This is also reflected in a complex $\alpha$ spectrum of $^{192}$At$m^{2}$; in addition to the 7435 keV and 7470 keV $\alpha$ decays, which have a comparable intensity, there are a few lower-intensity $\alpha$ lines, which are difficult to analyze in detail due to strong $\alpha + e^-$ summing effects.

An attempt was undertaken [29] to clarify the possible configurations by performing calculations of the energy splitting.
within some of these multiplets, similar to those presented for the $[\pi h_\nu/2 \otimes \nu i_{13/2}]_{11}$ multiplet in the odd-odd Tl and Bi nuclei in Ref. [27]. Unfortunately, it turned out that the results of the calculations are extremely sensitive to the parameters involving the $i_{13/2}$ neutron shell. This is because both $^{192}$At ($N = 107$) and $^{188}$Bi ($N = 105$) are in vicinity of the $i_{13/2}$ midshell at $N = 107$ where the proton-$\nu i_{13/2}$ coupling changes from the $\pi$(particle)-$\nu$(particle) character to the $\pi$(particle)-$\nu$(hole) character. This results in a strong degeneracy of the states within the multiplets for these configurations, which prevents us making any conclusions on their possible sequence. Therefore, we do not provide any configuration assignment for $^{192}$At$^{m_2}$ based on the comparison with theoretical calculations.

Due to the same reasons as mentioned above, no exact decay path could be established for the $^{192}$At$^{m_1} \rightarrow ^{188}$Bi$^{m_2}$ branch. As shown in Sec. III D the $I^\pi = 9^-, 10^-$ state at 165 keV partially decays by low-energy strongly converted transitions to a multitude of the lower-lying states, which in turn decay directly or indirectly to the $3^+$ $\alpha$-decaying isomer. However, due to lack of $\gamma$-$\gamma$ coincidences and complex $\alpha$-decay spectrum corresponding to this component, no further conclusions can presently be drawn.

V. CONCLUSIONS

Two $\alpha$-decaying isomeric states with half-lives of 88(6) ms and 11.5(6) ms were identified in the new isotope $^{192}$At, both of them having complex decay paths to the excited states in the daughter nucleus $^{188}$Bi. The latter is due to the expected complexity and multitude of the states, resulting from the $p$-$n$ multiplets in the odd-odd nuclei.

The $T_{1/2} = 88(6)$ ms high-spin $I^\pi = 9^-, 10^-$ isomer in $^{192}$At is well understood as mainly resulting from the $[\pi 2f_{7/2} \otimes \nu i_{13/2}]_{10^-}$ configuration, which confirms the expected onset of deformation in the At isotopes by approaching the neutron midshell at $N = 104$. No unambiguous conclusion on the configuration or $I^\pi$ value can be drawn for the 11.5 ms isomer.

Crucial for the present study was the understanding of the $\alpha$-$e^-$ summing in the PSSD. A more detailed study with much higher statistics and dedicated low-energy germanium detectors and low-energy electron detectors is necessary to resolve the complex decay pattern of these very neutron-deficient odd-odd nuclei.

Calculations of the proton-neutron coupling which would include the effect of deformation are clearly needed to understand the structure of the lightest odd-odd At isotopes.
